

Imagine you are designing a database for a specialized **hotel** catering exclusively to **singles** who are looking for an active and social ski vacation. The hotel offers different vacation **packages** that include both accommodation and ski pass options. The goal is to create a system that efficiently manages customer **reservations**, tracks package purchases, and allows the hotel to analyze **booking trends** and **customer preferences**. Each package contains specific type of room (e.g., **single deluxe, single standard, shared room**) and a corresponding **ski pass** type (e.g., **day pass, week pass, season pass**) for a predefined **price**. Each reservation is made for a specific **customer** and a specified **period**. A **reservation** can also reference a **package** which the customer buys, and **skipasses** for different **ski resorts** which the customer buys as part of the reservation. Each **skipass** allows access to a **ski resort** for a specific period of time. To help customers decide which skipasses to buy, the hotel provides information on the **difficulty level, location, and size** of each **ski resort**.

In general, the database will support:

- Managing customer details and reservations
- Tracking package purchases, including room type and ski pass selection
- Storing ski pass usage information

Add ReservationId Attribute
Add CheckInDate Attribute
Add CheckOutAttribute
Add CustomerIdentityProof
